ABSTRACT

Many methods have been proposed and tested in the past to obtain an optimal response for step inputs to automatic feedback control systems. Most of these methods have led to the use of sophisticated control devices ranging from small analog to large digital computers. Here the possibility of a simplified switching logic combined with an open-closed loop servomechanism is investigated. Deadbeat response to step inputs was the object of this study rather than a time optimal response. Two types of logic were investigated. A time invariant controller was analyzed. built and tested. The system works on the principle of constant switching times with the output being controlled by an open loop driving voltage which is proportional to the input step size. At the completion of the open loop mode of operation, the system is returned to the normal closed loop mode.

The writers wish to express their appreciation for the assistance and encouragement given them by Dr. John Ward, of the U. S. Naval Postgraduate School, in this investigation.

1. Introduction.

Numerous schemes have been applied to positioning feedback control mechanisms to obtain optimum response for step inputs. Some of the methods used have been (1) dual mode operation ¹ using a relay control computer which approximates the optimal switching line, (2) use of compensation networks to improve relay performance², (3) application of discontinuous damping to a relay servo³, (4) conditional switching techniques⁴, and others ^{5,6}. In general, the basic idea behind these various approaches is the desire to obtain deadbeat response in minimum time for a step input.

The time optimization requirement inherently requires a sophisticated controller that can compute the proper switching times accurately. A question

which might be asked is: "If the requirements for time optimization were dropped, retaining the provision for deadbeat response, would it be possible to design a simple controller for a second order system that would be of practical value?"

In this paper two approaches to the development of a simple controller for a second order system are investigated. In both cases the system operates in two modes, linear and nonlinear, which correspond to closed and open loop modes respectively. In the non-linear or open loop mode a driving voltage is applied to the plant for a prescribed amount of time. The voltage is then reversed until the system reaches an output which either equals or approximates the input. At this point the controller returns the system to the linear, closed loop, operation.

As previously stated, in both approaches investigated, relay switching is caused to occur on a time basis. One of these approaches sets the switching times proportional to the command signal while the other holds the switching times constant while setting the driving voltage. The latter scheme is suggested by the principle of superposition.

The system of Fig. 1 is the basic block diagram for both approaches. The step input commands are represented by R, the system output position by C and the output of the open loop controller by V. The plant is second order

and has the transfer function:

$$\frac{K/\pi}{s(s+1/s)}$$

The system is to be controlled by an open loop controller which functions on command signals only. Any load perturbations or other similar disturbances within the loop will not affect the controller.

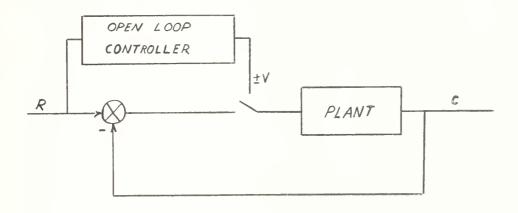

Fig. 1 - Basic System

The assumptions made for the theoretical investigations are (i) the system is linear, (2) the system is second order, (3) command signals are to be steps only and (4) new commands are not to be given until the previous command has been completely executed.

2. Time proportional to command signal.

With the output voltage of an open loop controller a constant in magnitude, there is a specific relation—ship for the time to reverse the polarity of the driving voltage and the time to return the system to normal linear operation in order to force deadbeat response.

By using an approximation to this relationship, a theoretical controller was derived. The system incorporating this controller was then investigated on the CDC digital computer.

For purposes of this investigation, the proposed system is to function as follows: At some time, t_o , a step command signal, \pm R, is applied to the system. Application of the command signal causes the loop to be opened and a voltage, \pm V, to be applied to the plant for a period of time, t_s . At time t_s the polarity of the signal is reversed for a period of time, t_r . The total time of nonlinear operation, t_t , is defined by:

$$(2) t_t = t_s + t_r$$

At time t_t the controller closes the loop returning the plant to standard closed loop operation. If at time t_t , the plant output has arrived at the desired position commanded by the input, then true deadbeat response has been achieved.

A digital program was written to compute the times $t_s \text{ and } t_t \text{ for various values of inputs. The system}$ parameters, K and \checkmark , as well as the applied voltage, \pm^V ,

were held constant. For the system under evaluation the following values were arbitrarily selected: $K/\!\!/ = 1, \ 1/\!\!/ = 5 \ \text{and} \ V = 100. \quad \text{Each combination}$ of t_s and t_t that results in deadbeat response specifies a command signal R. Thus, from the program data, a plot of t_s and t_t versus R was made for $0 \le R \le \mathcal{H}$ radians as shown in Fig. 2. From these data, t_s and t_t can be approximated by a straight line as shown in the figure. These straight line approximations of t_s and t_t can be evaluated in point slope form as:

(3)
$$t_s = .075 |R| + 0.05$$

(4)
$$t_t = .092|R| + 0.105$$

Since t_s and t_t are independent of the sign of the input, the magnitude of R is specified in the above equations.

It is immediately obvious from Fig. 2 that the straight line approximation is extremely poor for small inputs, but this problem can be eliminated if the system is held in closed loop for small inputs. Thus, in this system, the minimum step size for open loop operation would be about .25 radians.

Using the switching times determined from equations
(3) and (4), a program was written and appended to "Program

Analog" to study the performance of a system utilizing this type controller. Four runs were made with inputs of .5, 1, 1.5, and 2 radians. The resulting phase planes and time response characteristics as plotted by the computer are shown in Figures 3 to 10. By inspection of Fig. 2 it is possible to predetermine whether switching will occur early or late. For example, if the input is .5 radians, Fig. 2 predicts that both switching times, t_s and t_r, will be late and the system will overshoot. This is verified in Figures 3 and 4. If the input is 1.5 radians, it would be predicted that switching would be early. This is verified in Figures 7 and 8.

This approach does offer some improvement in time-to-steady-state over normal linear operation but it is limited to a comparatively small range of inputs. A controller that could vary the times of switching as specified by equations (3) and (4) would not be simple to construct, which is contrary to one of the main design objectives as set forth in section 1.

* * * * * * * *

7"Program Analog" was written by Dr. J. R. Ward of the U. S. Naval Postgraduate School. The program as used is shown in Appendix I.

3. Time invariant controller.

Assume that a given linear second order system is controlled in such a manner as to provide a deadbeat response for a step input. If the output of the linear system is proportional to a step input, then by the principle of superposition⁸, the output is doubled when the input is doubled. Furthermore, if the acceleration time, t_s, and the deceleration time t_r, are known for a specified step command, then it will be possible to obtain deadbeat response for all step commands if the switching times are held constant while the driving voltage is varied in proportion to the step command.

To determine the appropriate switching times, it is first noted that if the controller voltage is V, then the system output will, if the initial conditions are zero, be:

(5)
$$C(s) = \frac{KV/T}{S^2(S + 1/T)}$$

The step voltage +V is to be applied for a finite time, $t_{\rm S}$, and the step voltage -V is applied for the finite time, $t_{\rm T}$. If at $t_{\rm S}$ + $t_{\rm T}$, the output of the system is identically equal to the input, and the output rate is zero, then system response is indeed deadbeat. It is

* * * * * * * *

⁸M. E. Van Valkenburg, Network Analysis, Prentice-Hall, Inc., pp. 79-80.

now necessary to find the required conditions for such deadbeat response.

The inverse transform of equation (5) is:

(6)
$$C(t_s) = KV \left(T e^{-ty_F} + t_s - T \right)$$

To obtain the system rate at time t_s it is only necessary to take the derivative of equation (6). Thus,

(7)
$$\dot{C}(t_s) = KV(1-\epsilon^{-t_s/\eta})$$

The reversed voltage is now applied for a period t_r , and considering the initial conditions that exist at time t_s , it follows that the equations for system position and rate for $t_s \le t \le t_t$ are:

(8)
$$C(s) = \frac{VK/R}{S^2(S+V_R)} + \frac{C(t_S)}{(S+V_R)} + \frac{C(t_S)}{S(S+V_R)} + \frac{C(t_S)/R}{S(S+V_R)}$$

and:

(9)
$$\hat{C}(s) = -\frac{VK/r}{S(S+1/r)} + \frac{\hat{C}(ts)}{(S+1/r)}$$

or:

(10)
$$C(t_*) = VK \left(t_s - t_r + 1 \left[1 - e^{-t_0/4} \left(2 - e^{-t_0/4} \right) \right] \right)$$

and:

(11)
$$\dot{C}(t_0) = VK \left[-1 + \varepsilon^{-t_0/4} \left(2 - \varepsilon^{-t_0/4} \right) \right]$$

For deadbeat response the system rate, $\dot{\mathcal{C}}$, must equal zero at time t_t . Therefore, by setting equation (11) to zero, the exact relationship between the

acceleration time, t_s , and deceleration time, t_r , is obtained, namely:

(12)
$$e^{-t-/4} = 2 - e^{-ts/4}$$

To obtain the deceleration time required for any acceleration time, it is only necessary to take the natural logarithm of both sides of equation (12);

(12a)
$$t_r = T l_n (2 - \epsilon^{-ti/4})$$

To obtain the system output for deadbeat response in terms of $t_{\rm S}$ and $t_{\rm r}$, equation (12) is substituted into equation (10) which yields:

(13)
$$C(t_t) = VK(t_s - t_r)$$

Finally, the system output in terms of the acceleration time only can be found by substituting equation (12a) into (13) to give:

Thus by using a controller voltage proportional to \mathbf{R} , and by choosing $\mathbf{t_S}$ and $\mathbf{t_r}$ as calculated from equations (12a) and (14), deadbeat response can be achieved for any step input provided that the plant is adequately described by a (linear) second order transfer function.

4. A design example of the time invariant controller.

A logical sequence of manipulations to determine the proper switching times for a given linear second order system can be easily obtained from equations (12a) and (14). For purposes of illustration, assume that the system has the following characteristics:

K = 10 Maximum output desired = 10

T = 1.0 Saturation will occur if KV is greater than 100.

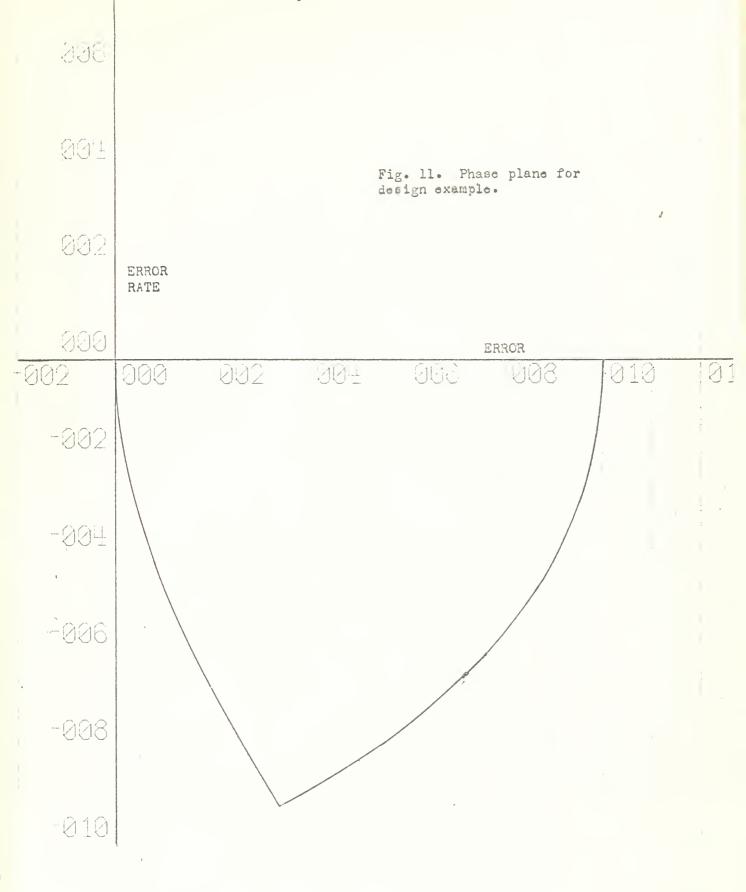

Using equation (14) with the constants given above and selecting a maximum applied controller voltage of 10 (to avoid the saturation non-linearity) a transcendental equation for the acceleration time, $t_{\rm S}$, is obtained:

(14)
$$10 = 100 \left[t_s - l_n \left(2 - \epsilon^{-t_s} \right) \right]$$

A value of t_s equal to .368 seconds will satisfy the equation. It is then necessary to find the deceleration time t_r . To do this, substitue time t_s into equation (12a) $t_r = l_n(2 - e^{-.368}) = .268 \, sec.$

The total time of open loop operation is then .636 seconds.

Using the above constants, the system equations were solved on the digital computer. Only one input was given to the system as other inputs would provide the same type of output changed by a constant only. Fig. 11 shows the computed phase plane response of the system.

RUN

5. Test of the time invariant controller applied to a d-c motor plant.

The controller analyzed in sections 3 and 4 above, is here investigated experimentally in relation to a DC motor plant which was predominantly second order and linear up to the saturation limit of the driving amplifier. Runs were made with various step inputs in both the time-invariant and standard closed loop modes.

The following operations by the open loop controller are required to test the theory:

- i) At time $t_{\rm C}$ a step input is commanded. The loop is opened and an open loop driving voltage is applied to the plant.
 - 2) At time ts the driving voltage is reversed.
- from the plant, the loop is closed, and the system returned to its standard closed loop mode of operation. The operations required were carried out by a timing device consisting of a variable speed D. C. motor geared to a shaft containing three "make and break" switches. The time of contact of these switches relative to each other was variable, that is, their relative anglular positions on the shaft could be varied. The switches were connected to relay circuits which accomplished the desired switching. Thus, relay switching times could be varied by adjusting the speed of the D. C. motor or by adjusting the relative angular position of

the "make and break" contacts.

Fig. 12 shows a block diagram of the experimental D. C. servo used for testing. When a step command is received, relay one switches to its normally open position. This is time t_0 . Relay two switches to its normally open position at time $t_{\rm S}$ to reverse the open loop driving voltage. A third relay, not shown in the figure, is used to return relays one and two to their normally closed positions at time $t_{\rm t}$.

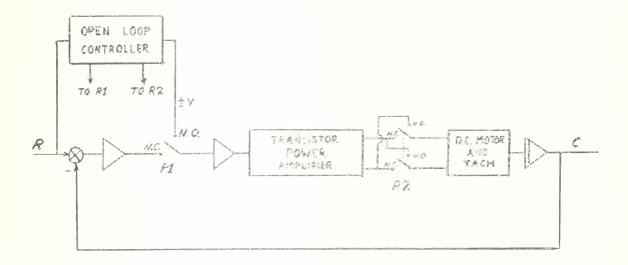

Fig. 12 D. C. Servo with a time invariant controller

The transfer function of the open loop system was
evaluated as:

$$\begin{array}{c} (17) & \frac{2.84/1.8}{5(5+1/1.8)} \end{array}$$

where the gain is 2.94 and the system time constant is 1.8 seconds. The system output position, C, was obtained by integrating the output of a tachometer geared to the driving motor. As a result, the system output was

evaluated in volts, and consequently, the command and output signals could be compared in volts rather than radians. Further investigation of the open loop system revealed that an open loop command signal of about eight volts would cause saturation in the transistor power amplifier. A schematic of this amplifier is shown in Fig. 13.

For the purpose of steady state accuracy, of primary importance in positioning systems, the closed loop gain was set at 29.4 or ten times greater than the open loop gain.

To simplify the construction of the controller, it was decided to obtain switching times such that a one volt input, R, would cause a one volt driving voltage, V. In other words, the constant of proportionality derived in equation (14) was made equal to one. This means that in equation (14), V=C, and t_S can be evaluated directly from that equation to yield the desired value.

(14)
$$C(a) = VK \left[t_s - t l_n (2 - e^{-t_s/\epsilon})\right]$$

$$\frac{1}{2.94} = t_s - 1.8 l_n (2 - e^{-t_s/\epsilon})$$

$$t_s = 98 \text{ sec.}$$

By using the value of $t_{\rm S}$ equal to .98 sec. in equation (12a), $t_{\rm r}$ is found to be .54 sec. The relay switching times were then set accordingly.

An input of three volts was used to check out the

-24-

Fig. 13. Schematic of translator amplifier.

switching time computed above. The response was not deadbeat. The switching times were then adjusted to obtain deadbeat response to the three volt input. The actual time of voltage reversal was 1.15 sec. compared to the computed .98 sec. The total time of operation was 1.65 sec. compared to the computed time of 1.62 sec. These differences were probably due primarily to the fact that the system was only quasi linear and second order, and the system gain and that constant were determined assuming a linear second order system.

A six channel Brush recorder was used to record the closed loop command signal, the open loop command signal, the system output and the system rate. Runs were made with the inputs varying from 1.4 volts to 10 volts. A standard closed loop response to the same step commands was also made for comparison purposes. Figures 14 through 21 show the responses obtained. Each page contains a time-invariant system response followed immediately by a standard closed loop response to the same signal. Table I is a comparison of the different runs.

Note.

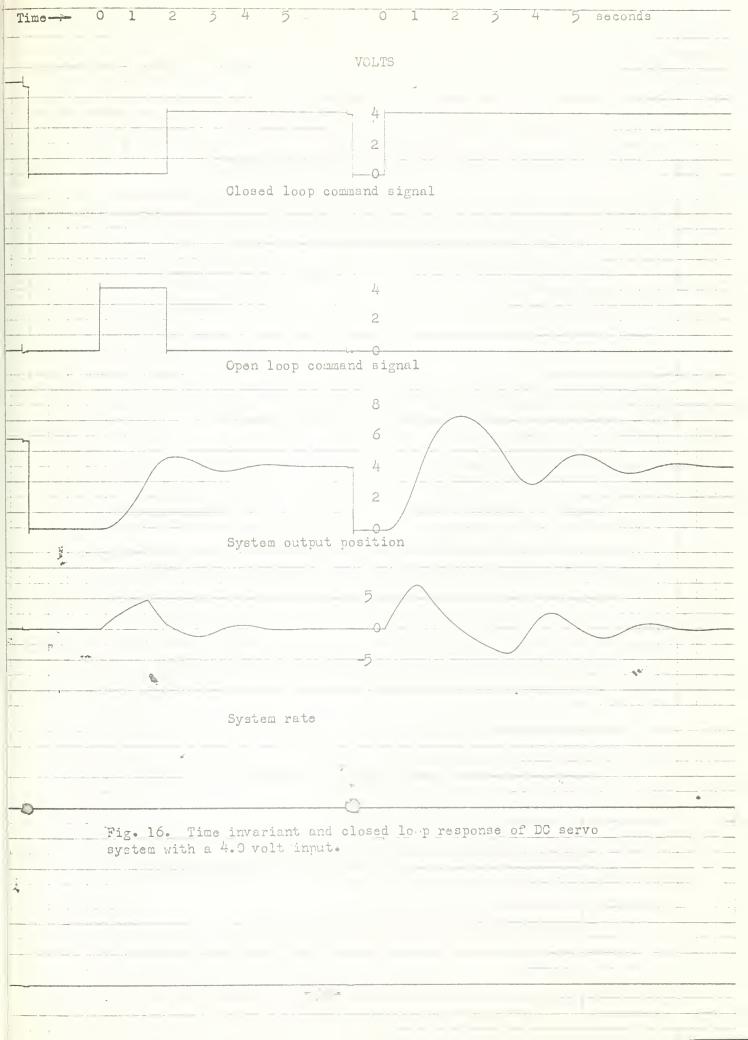

- 1. M_{pt} Ratio of maximum output to desired output.
- Time to steady state operation, taken to be when system is within at volts of command signal.
- 3. At s is defined as the difference between the times to steady state for the open-closed loop and of sed loop operation.

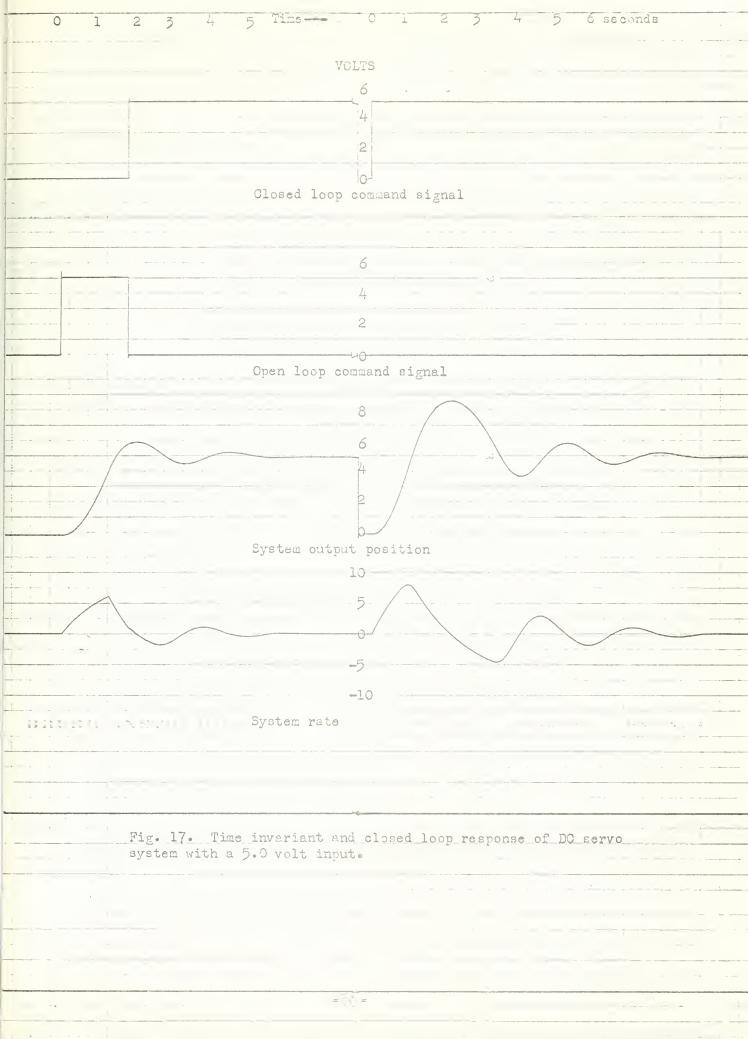

Deadbeat response, or near acadeat response, could be forced using the lime invariant controller if the command signals were to the range of 1.95 to 3.5 input volts. Figures 14 and 15 represent the typical responses retained in this wage. For these recordings the appear in the last feet and the opening signal.

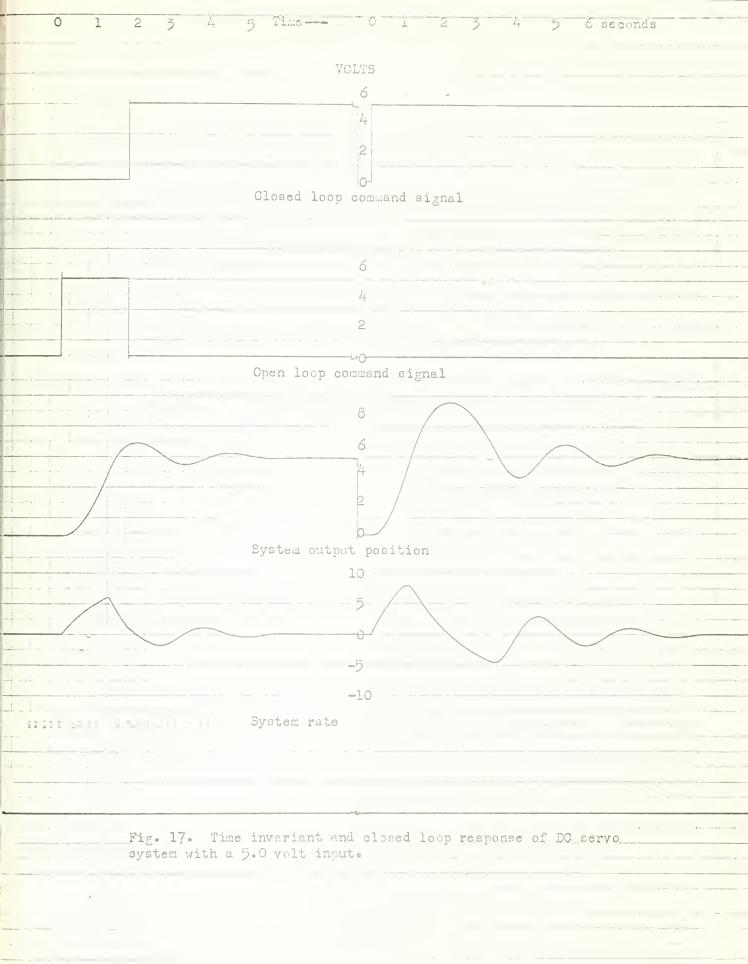

There makes the representation of the open loop remand signal.

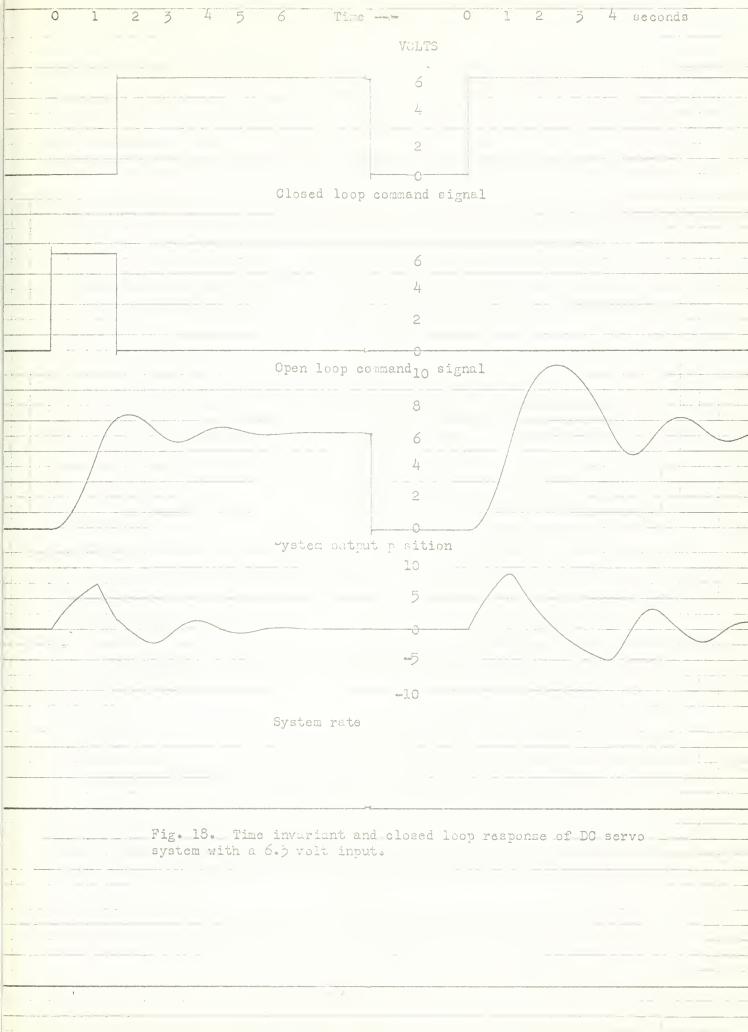

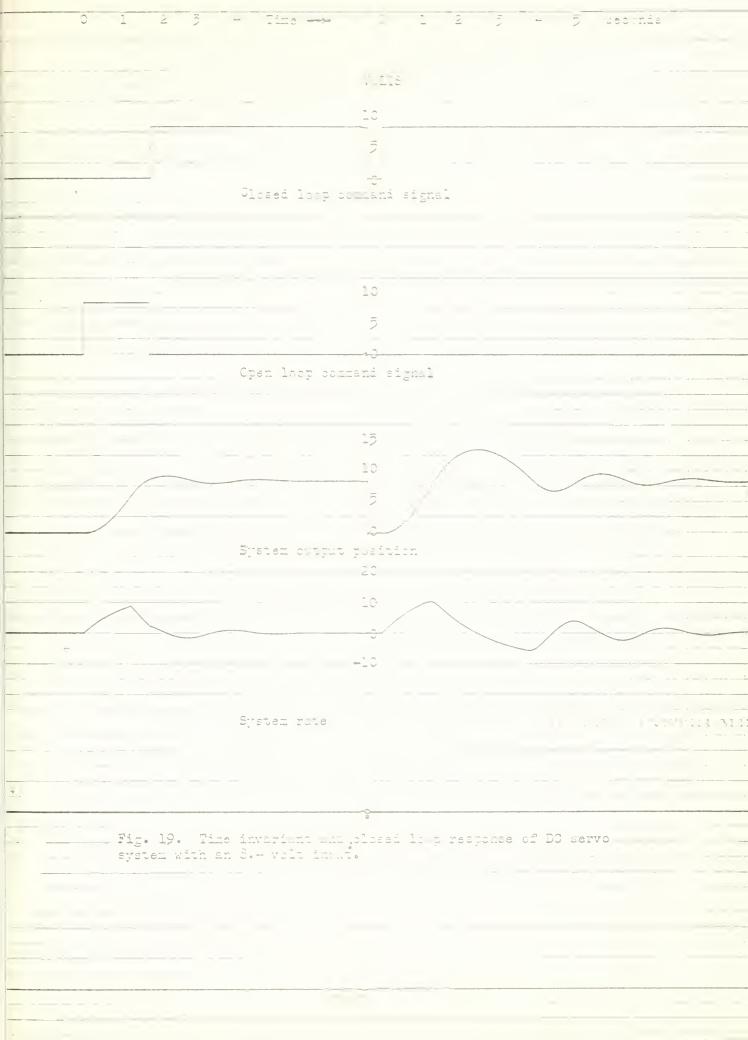

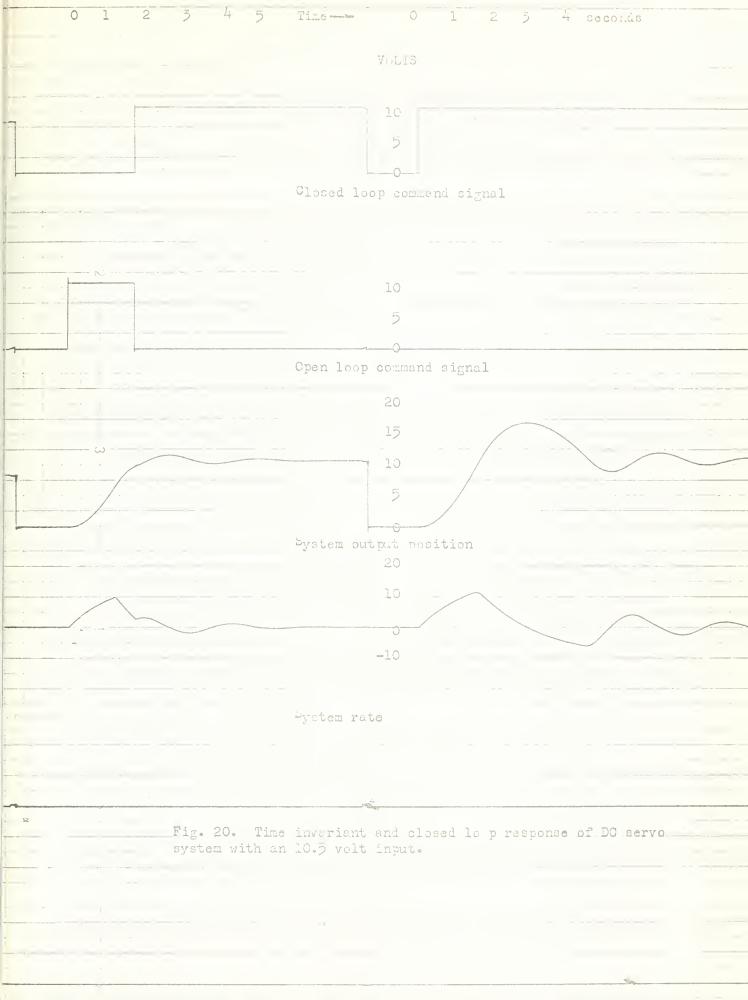

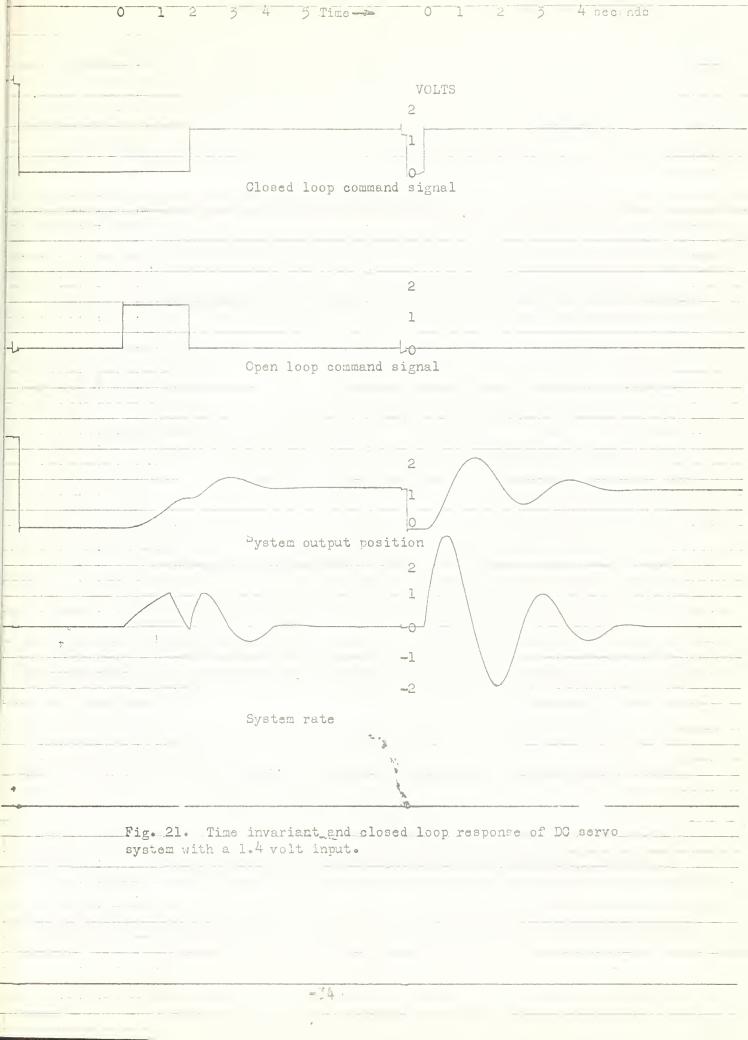

The controller reversed the input to the motor at the proper time but the reversal is not indicated on this trace. It was not possible to record the input to the motor (amplifier output) showing the reversal of driving voltage, because of grounding problems, & ground at the motor imput would cause one or both of the power transistors to burn out in the power amplifier. The third trace is the system output and the fourth trace, the system rate. The time to, the time at which the polarity or sign of V is reversed, is readily observed on the last trace, system rate, as there is a definite change in slope at that time. Time on all the traces reads from left to right with t signified by the commencement of the open loop command signal and t, by the end of this command and the start of the closed loop command signal.

It was mentioned earlier that an output signal of eight volts would saturate the power amplifier. It follows, then, that if C24, the amplifier will saturate when the driving voltage is reversed. The reason for this is that at the time of voltage reversal a back electrometrie force has built up in the motor which approaches the driving voltage. This back emf has the effect of increasing current requirement from the amplifier when the driving voltage is reversed. Therefore, at the time of switching, the system about tend toward accuration if the signal voltage is greater

The controller reversed the input to the motor at the proper time but the reversal is not indicated on this trace. It was not possible to record the input to the motor (amplifier output) showing the reversal of driving voltage, because of grounding problems. A ground at the motor input would cause one or both of the power transistors to burn out in the power amplifier. The third trace is the system output and the fourth trace, the system rate. The time ts, the time at which the polarity or sign of V is reversed, is readily observed on the last trace, system rate, as there is a definite change in slope at that time. Time on all the traces reads from left to right with to signified by the commencement of the open loop command signal and t, by the end of this command and the start of the closed loop command signal.

It was mentioned earlier that an output signal of eight volts would saturate the power amplifier. It follows, then, that if C≥4 , the amplifier will saturate when the driving voltage is reversed. The reason for this is that at the time of voltage reversal a back electromotive force has built up in the motor which approaches the driving voltage. This back emf has the effect of increasing current requirement from the amplifier when the driving voltage is reversed. Therefore, at the time of switching, the system should tend toward saturation if the signal voltage is greater

than four volts. This saturation caused a reduction in the braking or deceleration power available. From this it follows that the system output would tend to overshoot. These effects may be seen in Figures 16, 17, and 18. By analyzing the system rates at time ts and tt for these figures it can be demonstrated that saturation does occur in the time increment $t_s \le t \le t_t$. At time ts, for the three figures mentioned above, the system rate increased proportionately with the command signal as called for by the theory. Yet at time $t_{+,0}$ the system rate was larger than predicted meaning that the system did not decelerate sufficiently which resulted in overshoot at time t+. For example, the system rates at time ts and tt for the five volt input (Fig. 17) are 6.1 and .95 volts per second respectively. For an input of 6.2 volts (Fig. 18) one would predict by the principle of superposition that the rates would be increased by the factor 6.2/5.0 or would be 7.5 and 1.1 volts per second. Actually, Fig. 18 shows the rates to be 7.5 and 1.5 volts per second. The rate at time ts agrees with the theory but at time tt the rate differs by .4 volts per second. This difference can be accounted for by the saturation that occurs when the voltage is reversed.

When the system input exceeds eight volts, saturation is predicted at t_0 and at t_s . One would expect, therefore, that the system output would never reach the

desired point at time t_t or in other words, the system will have undershoot at time t_t . The reason for this phenomenon is that the driving voltage is never large enough to provide the response called for by the theoretical equations. The results of this type of saturation are shown in Figures 19 and 20. Fig. 20 clearly demonstrates the effect on system output.

Fig. 21 shows the response of the system with a small input, 1.4 volts. Here the system output, by time t_t , does not reach the desired value. The primary cause for this is that the small driving voltage is of insufficient magnitude to overcome the stiction and friction in the system.

From these experimental tests it can be seen that the time invariant switching scheme does provide deadbeat response over a range of inputs. If deadbeat response is desired in a positioning feedback control system, the method of time invariant switching can provide this in a given time increment over a designed range of inputs.

6. Test of the time invariant controller applied to an amplidyne driven motor.

The time invariant controller has been shown to work over a range of inputs with a quasi linear, second order system. One might now inquire as to its usefulness with a system that is quite nonlinear in that it exhibits hysteresis, excessive stiction, and saturation. To investigate this, a system was constructed that incorporated an amplidyne, a 4 HP dec shunt wound motor, and a permanent magnet, D. C. generator. The output of the generator, or tachometer, was integrated to simulate the system output. As in the previous experiment the system output and input was in volts. Fig. 22 depicts the system as set up in the laboratory with the relays performing the same functions as cut-lined in section 5. Fig. 23 is a picture of the system as it appeared in the laboratory.

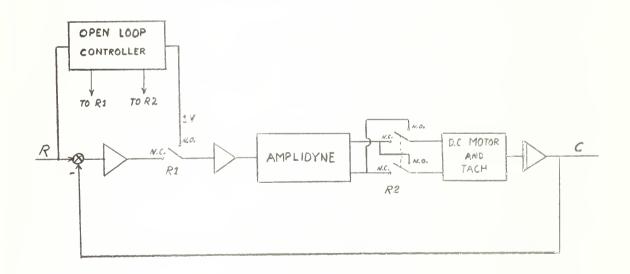

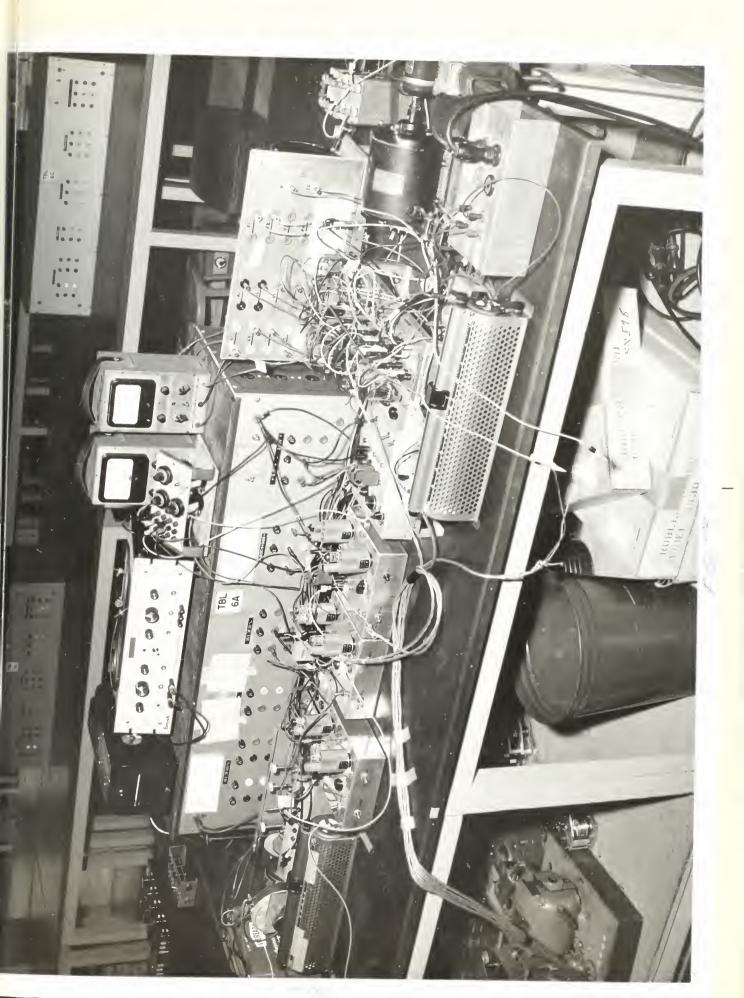

Fig. 22 Amplidyne driven motor servo system with time invariant controller.

A plot of the voltage input versus the tachometer voltage output for the open loop system appears on Fig. 24. Notice that at least two volts are required to start the system in motion and that at about six volts the system starts to go into saturation. The hysteresis loop is rather broad which could provide difficulty in system performance. From open and closed loop tests of the system, without the time invariant switching, the open loop transfer function was determined to be approximately:

$$\frac{10}{5(5+7)}$$

Depending on the test being conducted, the system gain varied from 100 to 115 and the reciprocal time constant from 6.9 to 7.5 inverse seconds.

Using the values of gain and the time constant from equation (7) and having a unity relationship between the open loop output and open loop driving voltage, $t_{\rm S}$ was determined from equation (14) to be about .33 seconds. Then $t_{\rm r}$, from equation (12a), was evaluated as .27 seconds. The system was run with an input step of four volts. The response was not deadbeat so the times of switching were adjusted to yield a near deadbeat response. The timing circuit controls were not fine enough to permit precise adjustments of the switching times. The adjusted times were then measured and found to be .38 second for time $t_{\rm S}$ and .09 second for $t_{\rm r}$.

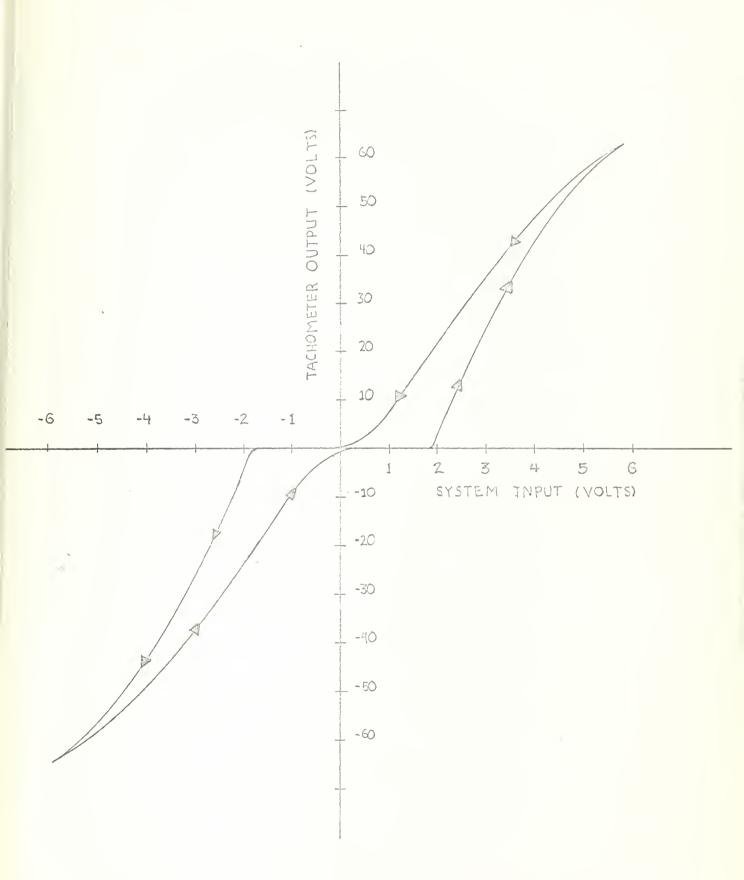

Fig. 24. Hysteresis loop of amplidyne driven servo system.

The acceleration time was .05 second longer than the computed value and the deceleration time was .18 second shorter than the computed value. This shorter deceleration time is probably due to the large friction that was present in the motors

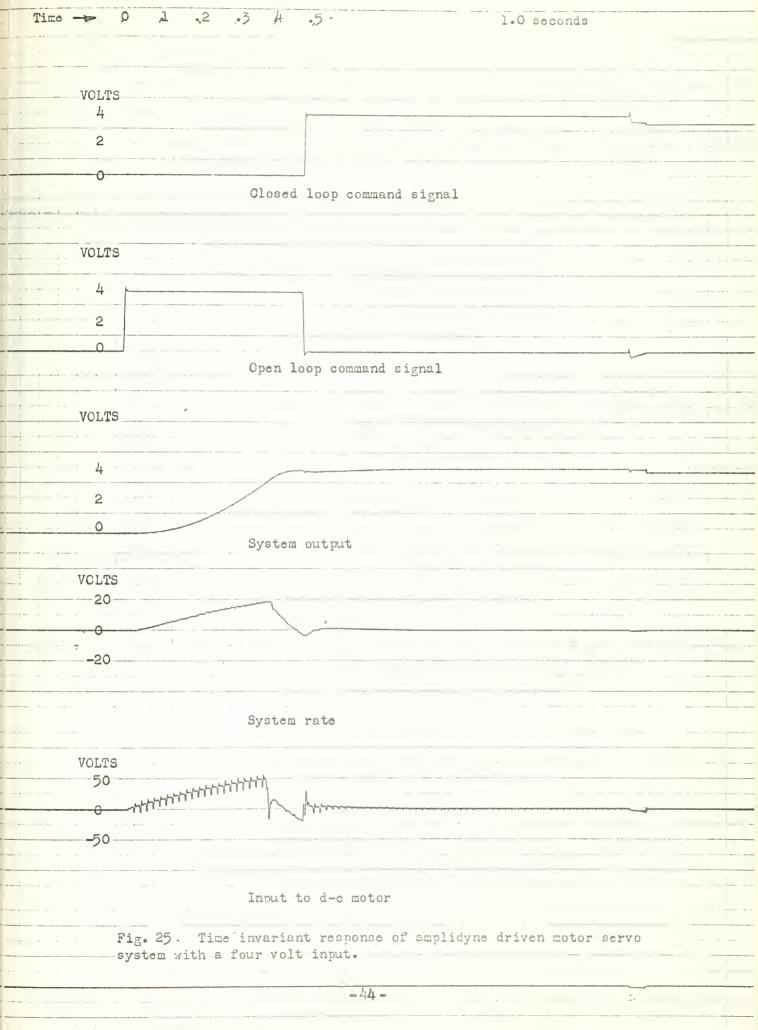

A Brush recorder was used to record the values of the closed loop command signal, the open loop command signal, the system output, the system rate, and the voltage applied to the motor. These recordings are shown in Figures 25 through 38. Following each time—invariant run to a given input, the system was run in the normal closed loop mode with the same quantities being recorded. A figure of the closed loop recording follows each time invariant figure. The maximum over—shoot and time—to—steady—state was evaluated for all runs and a comparison of the times to steady state was made. The results of this evaluation are tabulated in Table II.

Note:

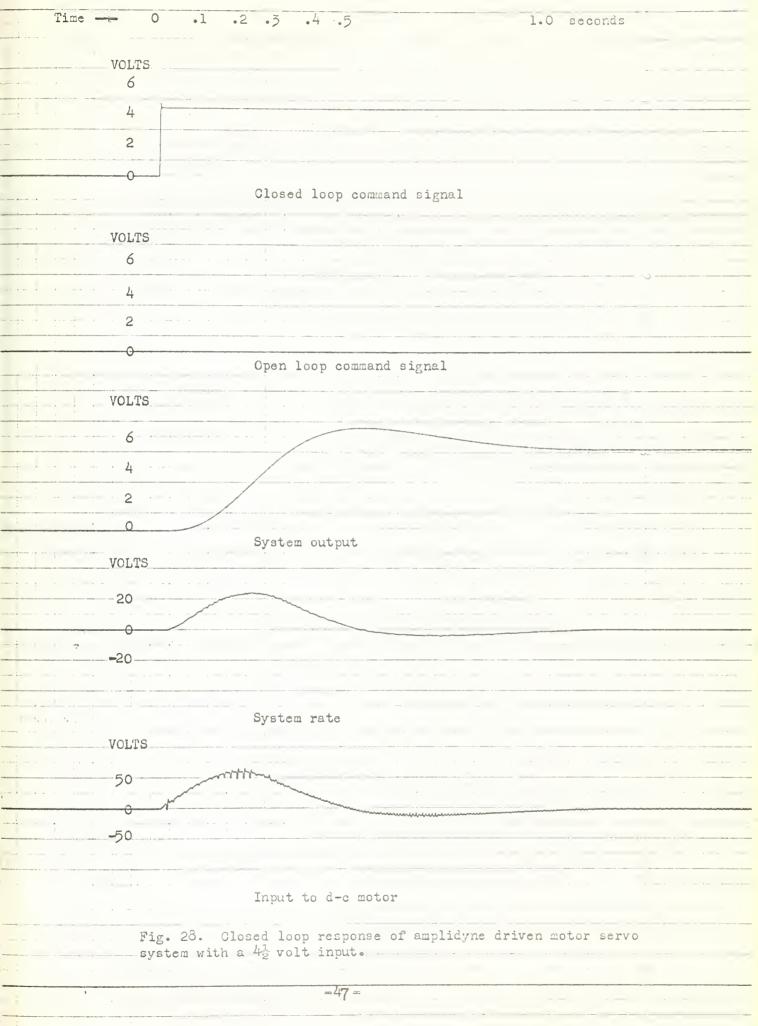

- 1. Mpt: Ratio of maximum output to desired output.
- 2. Time to steady state operation, taken to be when system is within .1 volts of command signal.
- 3. Δt_{SS} is defined as the difference between the times to steady state for the open-closed loop and closed loop operation.

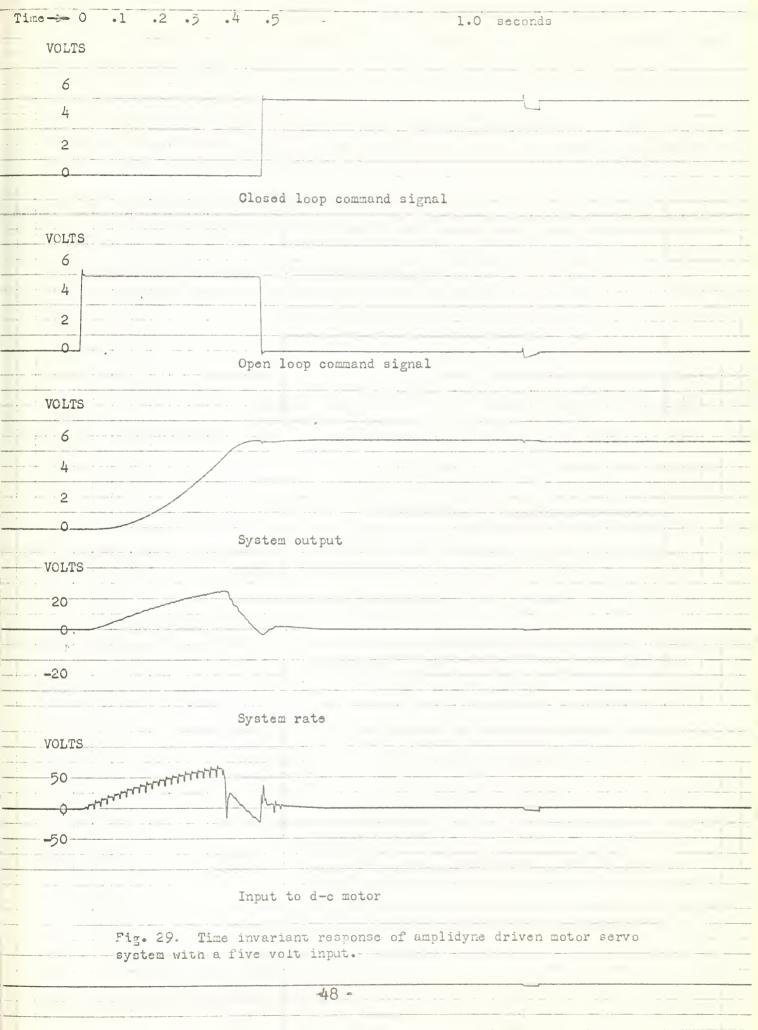

From the recordings it can be seen that the range from four to five volts the response was almost deadbeat. (Figures 25 through 30.) When the input voltage was in excess of five volts the system output started to overshoot the desired value at time t_t . As in

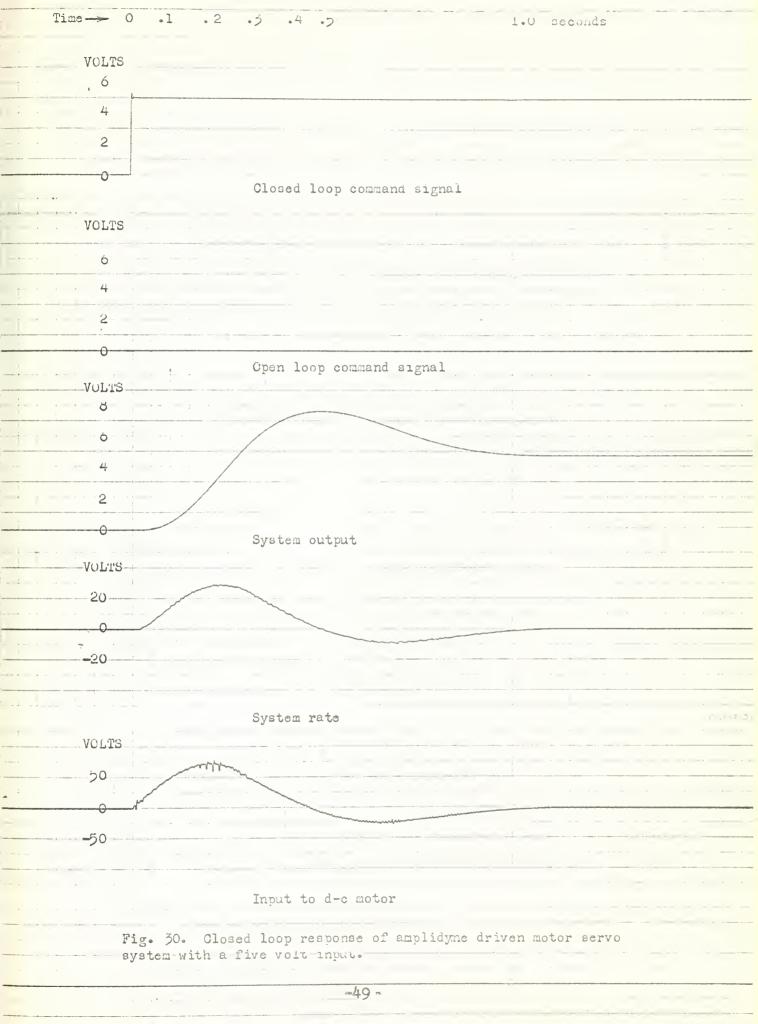

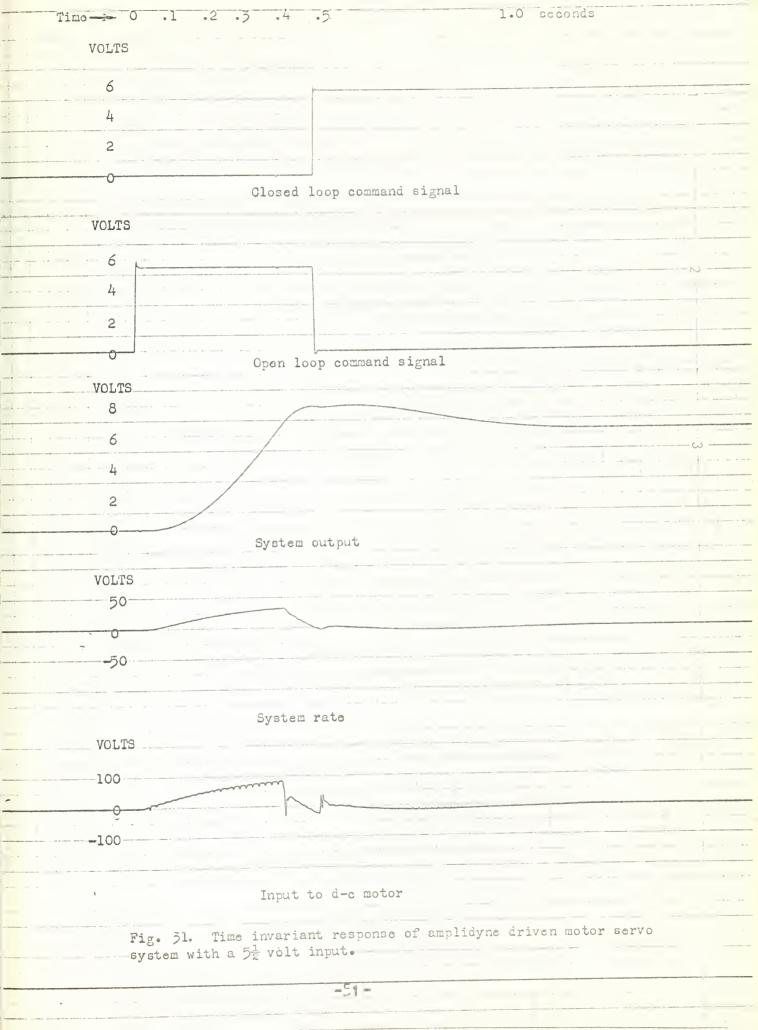

section 5 with the D. C. servo, this is due to saturation of the amplidyne when the driving voltage is reversed. This type of response is shown in Figures 31 through 34.

For step inputs less than four volts system performance deteriorated rapidly. This was due almost entirely to the excessive stiction and friction in the system. It was found that the system did not respond to a command less than two volts or about 30% of the operating range. The system response to inputs of 3 and 3.5 volts are shown in Figures 35 through 38.

As might be expected, the use of an open-loop controller with a far-from-ideal plant does not lead to acceptable performance.

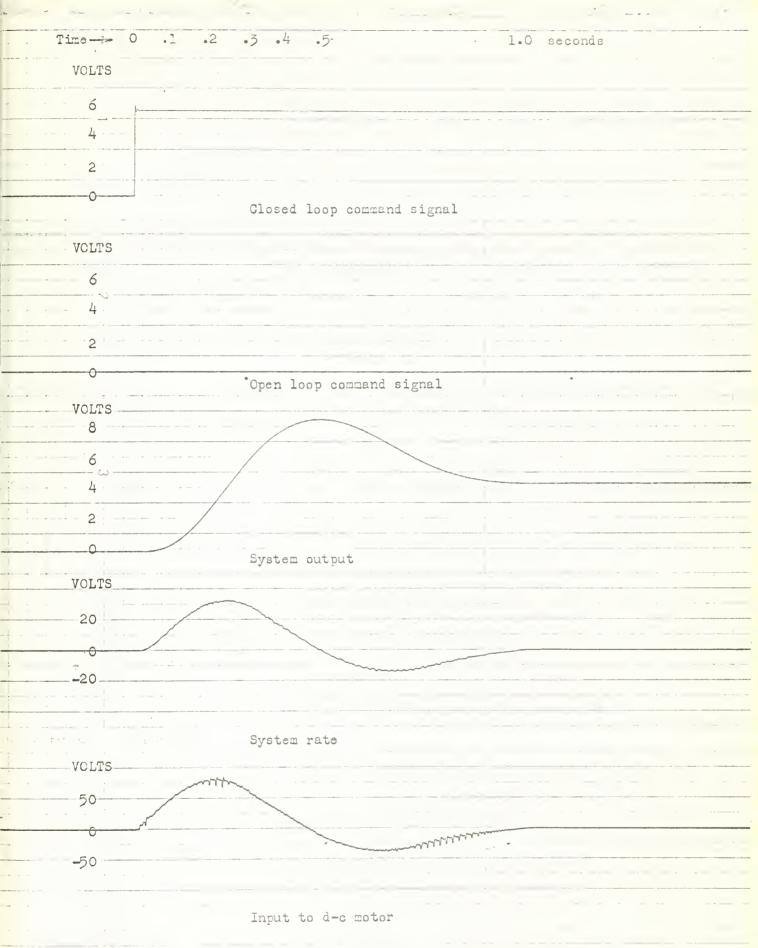

Fig. 32. Closed loop response of amplidyne driven motor servo system with a $5\frac{1}{2}$ volt input.

7. Conclusions.

In the search for a simple scheme to provide deadbeat response for step inputs to a second order system, attention was concentrated on an open-closed loop controller. For the system investigated, switching time in the open loop mode were fixed and the output from the controller to the plant was proportional to the magnitude of the step input.

Using this scheme, any linear system can be controlled with deadbeat response (Principle of superposition). To control the second order plant considered in this study only one switching point is required. The experimental program was intended to suggest the shortcomings of this approach when applied to a relay system with its non-linearities and higher order dynamics.

The first real system studied was relatively free from any non-linearities and provided near deadbeat response over approximately 50% of the designed operating range. A system with rather pronounced non-linearities was also chosen for study and provided near deadbeat response over less than 20% of the desired operating range. It is concluded, then, that if deadbeat or near deadbeat response is desired, the time invariant controller investigated in this thesis can be used to force this response in a linear system. With a non-linear system, the controller is of little use. In any event, the time of response to any size step requires the same interval of time for open loop operation.

APPENDIX I

PROGRAM ANALOG

A Control Data Corporation CDC 1604 digital computer is available at the U. S. Naval Postgraduate School. Dr. J. R. Ward of the Postgraduate School, Department of Electrical Engineering, has written a FORTRAN⁸ language program for this computer which simulates an analog computer. The program is referred to as Program Analog. It retains all the versatility of the analog computer and provides both a graphical and numerical output. With this program many of the problems of magnitude and time scaling as well as the difficulties in simulating nonlinearities associated with an analog computer are avoided. The program, which is reproduced in Figures 39 through 41, uses a modified Runge-Kutta integration scheme.

This program was used for the investigations carried out in section 2. Fig. 39 is the main part of the program. It consists of the necessary instructions for the analog simulation of a given problem and does not require any changes as the problem is varied. This part of the program may be thought of as the analog computer. Fig. 40 is the FORTRAN simulation of the

changed in the same manner as one would change the wiring on a problem board. Fig. 41, the data input, sets the initial conditions, potentiometer settings, problem time and provided means by which various output data can be obtained. A typical numerical output for a Program Analog problem appears in Fig. 42.

Figures 3 through 10 in the body of the these are typical outputs for the program.
